1. Background

Chronic Renal Failure (CRF) is a serious disorder. Four hundred thousand people are suffering from CRF in the United States of America. Its universal incidence is reckoned to be 260 people every year with an increase rate of 1.5% annually (1). These people will need hemodialysis, peritoneal dialysis or kidney transplant to continue their lives (2). There were 12500 patients under hemodialysis in Iran in 2006 (3). In spite of drastic advances in medical technology, the mortality rate of these patients has shown no meaningful decrease during 20 years and has been stabilized at 18% annually (4).

The principle of hemodialysis involves the clearance of solutes across a semipermeable membrane through diffusion and ultrafiltration mechanisms. The utilized membranes are classified into two main groups: lux which is based on using dialyzers with low permeability for water (5); and lux non-celluloses membrane with increased which is capable moderatelye molecules between 10000 to 15000 Dalton, including many of the inflammatory proteins, ßmicroglobulin and lipoproteins (6).

Some studies have suggested that high-flux membrane improves removal of moderatemolecules such as lipid profiles or homocysteine (7, 8) while other studies have concluded it has no significant impact on molecules such as homocysteine levels (9).

Inadequacy of dialysis is one of the main causes of death in hemodialysis patients. Some studies have suggested that high-flux membrane improves removal of moderatemolecules while other studies no significant on them.

Objectives: The aim of this study was to investigate the dialysis adequacy of low-flux versus high-flux membranes in Hemodialysis Patients.

Patients and Methods: Forty hemodialysis patients participated in this cross-over clinical trial. Two sessions of lux and lux membrane dialysis were performed in the first and second stage of the trial. In both stages blood samples before and after dialysis were taken and sent to laboratory for assessment. Blood urea nitrogen (BUN), KT/V (K = dialyzer clearance of urea, t = dialysis time, V = volume of distribution of urea) and the urea reduction ratio (URR) indexes used to determine dialysis adequacy. Data were analyzed by using SPSS16 and test and pair test.

Results: The mean of KT/V was 1.27 ± 0.28 in lux and 1.10 ± 0.32 in membrane which, differences statistically significant (P = 0.017). The mean of URR was 0.65 ± 0.09 in and 0.61 ± 0.14 in lux membrane which differences not statistically significant (P = 0.22).

Conclusions: The High-Flux membrane had better dialysis adequacy, so we suggest the use of High-Flux membrane in Hemodialysis centers.

Keywords: Hemodialysis; Dialysis Adequacy; High-Flux Membrane
significant effect on the adequacy of the dialysis (14). With regard to the available capacity of dialysis center across the country and the increasing need for further facilities, it is to limit the amount and time of dialysis to a optimal level. Therefore, reaching to certain level of dialysis adequacy is crucial and it has led researchers to projects to obtain this adequacy. In spite of the emphasis on the employment of -permeable membrane in the available research literature (15) and according to the crucial importance of using these membranes and the emphasis of the National Kidney Association of Iran on the necessity of these permeable membranes (16), there are still many wards utilizing -permeable membrane (17). The contradictory results of current published data prompted us to design this clinical trial study.

2. Objectives

This study was performed to compare the efficiency of -flu membranes in patients who referred to dialysis center of the Shahid Beheshti Hospital in Hamadan city, to investigate the proper membrane in order to increase the adequacy of dialysis and increase the level of health among these patients.

3. Patients and Methods

This research is a cross-over clinical trial study. Sample size was calculated based on a previous study in which House et al. (18) have studied the effect of high-flux vs. low-flux hemodialysis on homocysteine and lipids. Then 21 patients was estimated to be needed in each group based on the following parameters (β=0.20, α=0.05, 91 (variance of homocysteine in high-flux group) = 1.925, 62 (variance of homocysteine in low-flux group) =1.675, -1 - 2 (mean pre-dialysis homocysteine in high-flux group minus mean pre-dialysis homocysteine in low-flux group) = 2 (18). However, 40 patients were selected for more accuracy From 114 patients who assessed for eligibility, 74 patients excluded because of not having the inclusion criteria (n = 32), occurrence of exclusion criteria (n = 22) or declined to participate (n = 20).

Inclusion criteria were: participants' age to 60 years, dialysis treatment for at least 6 months with conventional HD, using fistula or graft as vascular access, at least twice 4-hour dialysis session per week, consciousness for participation in study, hemoglobin ≥ 9 mg/dL, interdialytic weigh gain less than 3 kg, no any neoplasia. Exclusion criteria were: hypotension (systolic BP ≤ 90 mmHg), acute clinical conditions (myocardial infarction, congestive heart failure, stroke, recent surgery, or severe sepsis) during the study, any vascular access dysfunction, discontinuation of dialysis less than 4 hours, reduction in consciousness, restlessness and agitation, severe nausea and vomiting during dialysis, starting other treatments.

During the research, the dialyzer was fixed and 500 mL/min bicarbonate solution as dialysate. The blood flow rate was fixed for each patient. units of heparin per session as anticoagulant were used. The sodium density of dialysate was 135–145 meq/L with a stabilized temperature at 37. The amount of food and liquid taken for each participant throughout the study were the same and controlled. No blood transfusion was given to any patient during the study period.

3.1. Interventions and Comparison

In the first stage all participants underwent dialysis two sessions per week in accordance with the guidelines of adequacy and efficiency of dialysis (16) by utilizing -membrane (FRS made by the Soha Co., Iran); then, they attended another two sessions of dialysis in the following week by utilizing the -membrane (FR50, made by Soha Co., Iran).

The members of the second group were treated similarly except that they attended the dialysis with the utilization of -membrane based on the guidelines of the adequacy and efficiency of dialysis provided (19). Blood samples were taken in the second dialysis session of each stage the first sample was taken in the onset of dialysis from the arterial line (before dialysis sample) and the second sample was taken from the arterial line at the end of the dialysis session after 2 minutes decreasing the blood flow rate to 80 mL/min (after dialysis sample). The samples were labeled and sent to the laboratory to determine the level of BUN. The lab technician was not informed about the study groups. The lab process and the technician in-charge for all samples were the same.

The (URR) and the KT/V were utilized. In KT/V measure, K stands for the dialyzer clearance (mL/min), T stands for the time of dialysis (min), and V, the bottom part of the fraction, is the distribution of urea which is equal to total body water (19). To determine the adequacy of hemodialysis based on the KT/V, the Daugirdas formula was used (20-22).

Data were collected by a questionnaire for demographic data (age, gender, interdialytic weight gain, kind of vascular access, dialysis history, etc.) and a checklist to record the BUN before and after dialysis, dialysis session time, blood flow rate, dialysate flow rate and the ultrafiltration rate.

3.2. Ethical Considerations

The Research Council and the Human Research Ethics Committee of Hamadan University of Medical Sciences approved the study protocol and its ethical considerations (D/P/16/35/9794). To begin the study, the researcher explained the study process to the patients and they
signed a written informed consent. The patients were also assured about data confidentiality, safeness of the study, and their right of not to participate. We also observed all ethical issues in accordance with the last version of the Helsinki Declaration.

3.3. Statistical analysis

Data were analyzed by using SPSS version 16 and descriptive statistics (frequency, and standard deviation) and inferential statistics (test for comparison of KT/V, URR and BUN in and membranes and -test for comparison of pre and postdialysis BUN in membranes).

The dialysis adequacy was classified into three groups: inadequate dialysis (KT/V ≤ 0.89, or URR ≤ 0.60); relatively adequate dialysis (KT/V = 0.90 to 1.29 or URR = 0.61 to 0.70); and the totally adequate dialysis (KT/V ≥ 1.3, or URR ≥ 0.70). Statistical significance was considered at value < 0.05.

4. Results

Most of participants (67.5%) were male with the mean of 47.56 ± 10.79 years, 87.5% of the participants used fistula and 12.5% graft for dialysis. of participants were urban and 15% were living in rural areas. of the participants had dialysis history for a period of three to four years. The mean of interdialytic weight gain was 1.91 ± 1.07 kg. The blood flow rate was between 220-300 /min with a mean 271 ± 18.91 mL/min. (Table 1).

*4 mean ± SD.

The mean blood urea nitrogen (BUN) before-dialysis was 93.90 ± 20.51 mg/dL, which reduced at the end of the dialysis to 36.87 ± 13.16 mg/dL. The observed difference was statistically significant, \(P < 0.001\). Furthermore, the mean of the BUN before -dialysis was 95.32 ± 19.69 mg/dL, which reduced to 32.35 ± 8.83 mg/dL at the end of dialysis was statistically significant \(P < 0.001\) (Table 2).

The mean of BUN before using the - (93.90 ± 20.51 mg/dL) and -membrane (95.32 ± 19.69 mg/dL) were not significantly different \(P = 0.725\). Although the mean of BUN after -dialysis (32.35 ± 8.83 mg/dL) was lower than the mean of the BUN after -dialysis (36.87 ± 13.16 mg/dL), this difference was not statistically significant \(P = 0.071\) (Table 2).

The URR was 60% to 80% for of the patients in -dialysis;
whereas, 70% of the patients in dialysis had the URR 60% to 80%. The mean of URR for patients in dialysis was 0.65 ± 0.14, and in the dialysis was 0.65 ± 0.09. Although the adequacy of dialysis based on URR was higher in the dialysis, the difference was not statistically significant ($P = 0.211$) (Table 3).

$\chi^2 = 9.839, P = 0.043$

$\chi^2 = 7.180, P = 0.127$

Data are presented as No. (SD).

In dialysis, the most frequent (32.5%) of KT/V was 1.2 to 1.4 (mean 1.27 ± 0.28); while, in dialysis the most frequent (30%) of KT/V was 1 to 1.2 (mean 1.1 ± 0.32) differences was statistically significant ($P = 0.017$) (Table 4) reveals the relative adequacy of dialysis. High-Flux dialysis was totally adequate in 50% of the cases and it was inadequate in 10% of patients based on KT/V. The utilization of dialysis showed the adequacy only in 20% of cases and it was inadequate in the other 20%. In estimating the adequacy of dialysis based on the URR, in dialysis, 25% of participants had totally adequate dialysis and 27.5% had inadequate dialysis. While in the dialysis only 5% of participants had totally adequate dialysis and 42.5% had insufficient adequacy of dialysis (Table 5).

5. Discussion

In the present study, the mean adequacy of dialysis by using high-flux membrane based on KT/V was 1.10 ± 0.32 which was still far from the minimum level introduced by the Office of Special Disease of the Ministry of Health of Iran (KT/V = 1.20). Hoojat investigated the adequacy of dialysis in 68 Chronic Renal Failure patients in Jahroom, Iran. His findings revealed that the measures of KT/V was less than 0.8, in 35.29% of patients and URR index was less than 65%, in 58.82% of patients which were both less than the minimum level. The mean of dialysis adequacy based on KT/V was 0.963 ± 0.75 which revealed an unacceptable dialysis adequacy (23).
Moslem et al. (2008) investigated the adequacy of dialysis in Ghonabad, Iran. In this research, the adequacy of both and lux membrane was investigated in two groups (each group 15 participants). The mean of KT/V in group was 1.44 ± 0.32 and in 80% of patients the adequacy of dialysis was over 1.2 (24).

Although in this study, mean of KT/V in high-dialysis was more than our study (in our study 58.4% of patients had KT/V ≥ 1.2), and was not statistically different from the -dialysis, in our research the adequacy was significantly better in -dialysis. In Moslem et al. study, the vascular access, blood flow rate, and the type of used membrane were not mentioned. Furthermore, the size of the sample is relatively smaller than our study.

Ponikvar et al. investigated the comparative efficiency of the with lux membranes in acute renal failure in intensive care units. The results showed no statistically significant differences in using these two membranes which could reveal the inadequacy of -membrane for these patients (25). This finding may relate to the acute or chronic phase of the disease. In chronic status of renal failure due to the accumulation of waste materials, the efficiency of -membranes would be obvious compared to the -membranes.

El-Wakil et al. investigated the effect of High-Flux versus Low-Flux hemodialysis on serum, advanced oxidation protein products and protein carbonyl. In the first stage, 20 patients were dialyzed by using -membranes for a period of weeks. The second phase, were maintained on Low-Flux dialysis for same period of 8 weeks. The results revealed the -was successful in reducing the and protein carbonyl. However, the high--membrane did not have any observable influence on reducing the advanced oxidation protein products. In the same study, however, the use of -membrane revealed all three indexes were significantly increased. The findings confirmed that the use of high- -membrane will significantly better the diffusion of uremic toxins (22). This finding was with our study.

Oates et al. investigated the effects of on and the responses of erythropoietin. Also, they the influence of - and -lux membranes in dialysis adequacy. The results showed no significant difference between membranes (26). But Eknoyan et al. found that -membrane improves the adequacy of dialysis in chronic renal failure (27). The findings of the present research are with the findings of this study.

Makar et al. compared the roles and influences of these two membranes on children hemodialysis patients. They reported no statistically significant differences in adequacy of these membranes (28). However, in our study this difference was significantly important and provided supports for the use of -membranes. Makar et al. study was conducted with participating children who requires certain arrangements such as low blood flow rate, low dialysate flow rate and used small diameter membranes to make it tolerable for the children. These factors could have influences on the adequacy of dialysis.

Santoro et al. investigated the effect of high-flux hemofiltration versus low-flux hemodialysis on mortality index. The results revealed that -hemofiltration increased the survival and decreased in plasma level significantly (17). This study further supports the adequacy of -membrane.

In another study, Mohseni and Ilali investigated the adequacy of hemodialysis using bicarbonate dialysate in Sari, Iran with 50 participants. The findings revealed that the mean of KT/V was 0.92 ± 0.26 and 86% of patients had inadequacy of dialysis (KT/V > 1.2). Furthermore, the mean of URR was 47.84% and 90% of participants (45 patients) had URR index less than the minimum standard level (65%). Of the unacceptable quality of dialysis in most patients, they recommended periodical evaluation of the quality of dialysis as well as conducting comprehensive studies in order to determine viable methods to the adequacy of dialysis (30).

Malekmakan et al. found that only 32.1% of renal failure patients achieve the optimal KT/V level and have recommended using advanced dialyzers (31). In our research, however, the -group revealed 35% of adequate dialysis of KT/V > 1.2 and in -group over 60% of patients had KT/V > 1.2. These findings confirm the crucial importance of -membranes in achieving the requirement of optimal dialysis.

Other Iranian research findings revealed inadequacy of dialysis in most centers across the country, such as the study of Raiesifar et al. (2010) in Abadan using low-membranes. The mean of KT/V was 0.9 ± 0.21 and the inadequacy of dialysis was 97.8 % (32).

Taziki and Kashi reported the inadequacy of dialysis in Sar, Iran, by using -membranes and 58% of patients had KT/V less than 1 (33). Another study in Birjand, Iran, with participation of 50 patients showed that 70% of the patients had KT/V 0.9 to 1.2, and 66% of patients had URR between 61% to 70% (30). In our research, in -membrane the mean of KT/V was 1.1 ± 0.32 and the ratio of inadequacy was 20%, also another 20% of the participants had KT/V less than 1, and 55% of them showed URR more than 60%. For the -membrane, the mean of KT/V was 1.27 ± 0.28, and the inadequacy was seen in 10%, also 17.5% of patients had KT/V less than 1, and 72% had URR<60%.

The mean of KT/V in studies conducted in the USA and Japan was 1.30 ± 0.29 and 1.30 ± 0.2, respectively (31, 32). Other studies, revealed that 60% to 80% of patients had KT/V equal or more than 1.2 (33). These values were than the values in our country as presented in the literature, showing the inefficient strategies in Iranian dialysis centers. One of the reasons which significantly to the observed efficiency and adequacy of dialysis in developed countries, is the more of high-flux membranes; while, in our country mostly used low-flux membranes in dialysis centers and the patients do not ask for them due to their unfamiliarity or carelessness.

Among the other reasons of the low quality of dialysis in Iran compared to the developed countries, are the
vascular access problems (recirculation), the duration of the dialysis session, and the lack of sufficient number of dialyzers (30), the blood flow rate, the blood sampling method for determining the BUN, insufficient surface of the membranes and the type of membranes (12). Suitable setting and priming of membranes and hemodialysis set and remove the air from them as well as -membranes or suitable size could increase the dialysis adequacy.

The use of membranes will improve the adequacy of dialysis. Moreover, due to the characteristics of these membranes in removing the middle size and large size molecules such as , using High-Flux membranes thus allows improved removal of a wider spectrum of uremic toxins which may improve the quality of life of patients on chronic hemodialysis. According to the result of this study, these membranes in other dialysis centers.

The limitation of study was short followup. It is recommended comparison of High-Flux and Low-Flux membranes performed in long period (34-36).
